In this paper we examine the methodology for extracting the Knudsen number (K) and the ratio of shear viscosity to entropy density (η/s) developed by Drescher *et al* [1]. The final result for η/s turns out to be quite sensitive to Glauber parameters, and particularly the parameter x which controls the balance between N_{part} and N_{coll} . We also explore how alternative formulations of the functional relation between the elliptic flow and Knudsen number ($K = \lambda/\bar{R}$) impacts the physics conclusions, based on Padé approximants. Finally, we extend the calculation to include a limiting minimum value on the mean free path proportional to the DeBroglie wavelength. These results emphasize the importance of clarifying the initial state used in different calculations, as well as the ambiguities inherent in using a transport approach in a strongly-coupled regime.

INTRODUCTION

The medium created in heavy ion collisions at the Relativistic Heavy Ion Collider (RHIC) defied expectations by showing a strong collective flow, characteristic of a perfect fluid [2, 3, 4, 5]. This behavior is particularly striking since even a modest amount of viscous damping, parametrized as the ratio of shear viscosity η to the entropy density s , is predicted to result in large deviations from ideal hydrodynamics [6]. Several methods, each subject to as-yet uncontrolled systematic uncertainties, have been developed to estimate the value of (η/s) from the experimental data on collective flow [1, 7], fluctuations [8], and heavy quark transport [9]. A parallel effort in this direction has been the development of hydrodynamic codes in two and three dimensions with a properly causal and stable relativistic treatment of viscous effects to second order in the velocity gradients [10, 11, 12, 13, 14]. While recent work has resulted in a greatly improved understanding of the various formalisms used by these authors [15], and direct comparison to experimental data has been made for a range of values in η/s , there remains considerable debate regarding the sensitivity to initial conditions, equations of state, and precise freeze-out conditions.

These different approaches are in large part motivated by the conjecture [16] that there is a fundamental bound on the viscosity to entropy density ratio: $\eta/s \geq 1/4\pi$. Intriguingly, all methods produce values for η/s from the RHIC fluid that are within factors of 1-4 of the bound. This brings into sharp focus the need to understand in detail the utility and the limitations of each method. In

this paper we concentrate on the approach of Drescher *et al.* [1], which provides a useful framework for parameterizing departures from ideal hydrodynamic behavior in terms of the Knudsen number $K \equiv \lambda/\bar{R}$, where λ is the mean free path of particles or quasi-particles in the system and $\bar{R}$ is a characteristic measure of the system size.

It has been realized since the earliest applications of hydrodynamics to nuclear collisions (see the first two footnotes of Ref. [17]) that the determination of K is directly related to the viscosity of the fluid. For sufficiently small values of K the hydrodynamic limit is reached, but larger values imply the presence of a non-trivial mean free path, leading to the damping of momentum anisotropies, and thus deviations from ideal fluid behavior. In Ref. [1] the Knudsen number is directly related to the elliptic flow scaled by the initial state eccentricity v_2/ϵ , thereby providing a convenient link between the experimental data and the transport properties of the medium.

METHODOLOGY

In this section we review the previous extraction of the Knudsen number and the the ratio η/s as formulated in Ref. [1]. In doing so, we demonstrate the sensitivity to various assumptions at different steps in the calculation. Following Bhalerao *et al.* [18], Ref. [1] takes the characteristic size of the system $\bar{R}$ as the scale of the strongest gradient in the initial matter configuration of the system,

estimated by

$$\overline{R} = \frac{1}{\sqrt{1/\langle x^2 \rangle + 1/\langle y^2 \rangle}} \quad (1)$$

This expression for $\overline{R}$ is used to determine the Knudsen number, which in turn is assumed to describe deviations of the elliptic flow parameter (v_2) scaled by the initial eccentricity ϵ from the corresponding ratio for ideal hydrodynamics (v_2/ϵ)_{ih} via

$$\frac{v_2}{\epsilon} = \left(\frac{v_2}{\epsilon}\right)_{ih} \frac{1}{1 + K/K_0} \quad (2)$$

where K_0 is a parameter estimated to be approximately 0.7 from varying the particle cross-section in a 3D transport code [19], or by comparison to a Monte Carlo solution of a two-dimensional Boltzmann equation [20]. The parametric dependence on K in Eqn. 2 is not directly motivated by an underlying microscopic theory, but rather was proposed in Ref. [18] to have the correct limits in the two extremes of large and small K . In the limit of large mean-free path (large K) $v_2/\epsilon \propto 1/K$, while in the small mean-free path (small K) limit v_2/ϵ approaches the limiting ideal fluid or hydrodynamic value (v_2/ϵ)_{ih} with corrections linear in K . If the functional form of Eqn. 2 was unique (to be discussed below), then it is clear that by combining the value of (v_2/ϵ)_{ih} calculated using ideal hydrodynamics with an experimental measure of v_2/ϵ would permit a direct determination of K (albeit with the embedded uncertainties of hydrodynamic calculations mentioned in the introduction). Even more appealing is the possibility developed in Ref. [1] of directly determining both (v_2/ϵ)_{ih} and K by fitting the experimental data on v_2/ϵ as a function of centrality.

The Knudsen number varies with centrality both directly via associated changes in $\overline{R}$ and indirectly through changes in the particle number density n :

$$\frac{1}{K} = \frac{\overline{R}}{\lambda} = \overline{R}n\sigma \quad (3)$$

where σ is the effective inter-particle cross-section. Please note that having well-defined values for n , σ and λ implicitly assumes classical ballistic transport. The prescription for estimating n from the experimental data comes from Ref. [18]

$$n = \frac{1}{S_T \tau} \frac{dN}{dy} \quad (4)$$

which relies on calculations (for example from Monte Carlo Glauber [21]) to determine the transverse area S_T of the system and the assumption of Bjorken expansion[22] with τ as an appropriate proper time in a rapidity slice. The characteristic time over which the gradients develop was assumed in Ref. [18] to be $\tau = \overline{R}/c_s$

where c_s is the speed of sound from the equation of state, giving:

$$n(\tau = \overline{R}/c_s) = \frac{1}{S_T} \frac{c_s}{\overline{R}} \frac{dN}{dy} \quad (5)$$

and thus (by Eqn. 3):

$$\frac{1}{K} = \frac{\sigma c_s}{S_T} \frac{dN}{dy} \quad (6)$$

Note that with these assumptions the Knudsen number no longer requires knowledge of $\overline{R}$. One can then eliminate the Knudsen Number entirely and write Eqn. 2 in terms of these new quantities.

$$\frac{v_2}{\epsilon} = \left[\frac{v_2}{\epsilon}\right]_{ih} \frac{1}{1 + \frac{1}{K_0(\sigma c_s)(\frac{1}{S_T} \frac{dN}{dy})}} \quad (7)$$

which indicates that fitting plots of the experimental values of v_2/ϵ as a function of another ‘experimental quantity’ $\frac{1}{S_T} \frac{dN}{dy}$ can be used to determine (σc_s) and $(\frac{v_2}{\epsilon})_{ih}$. This approach is then applied to PHOBOS measurements of v_2 in Cu+Cu and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV for unidentified hadrons at pseudo-rapidity $\eta = 0$ as a function of the number of participating nucleons (N_{part}) [23, 24, 25]. We note here and below that the dN/dy that appears in these equations is that for total particle (presumably parton) rapidity density, so that further (plausible) assumptions are required to express this in terms of the experimentally measured charged-particle pseudo-rapidity density $dN_{ch}/d\eta$.

DETAILS OF THE INPUT PARAMETERS

In this section we describe the uncertainties associated with the determination of the eccentricity-scaled elliptic flow v_2/ϵ and the parton transverse areal density $\frac{1}{S_T} \frac{dN}{dy}$. Close examination finds that the PHOBOS data presented in Fig. 1 of Ref. [1] appears quite different from what is nominally the *same* data presented in Fig. 6 of Ref. [24]. This is explained primarily by the fact that while the extraction of the Knudsen number is based on experimental data, the approach relies on various geometric quantities (e.g. the area S_T , the eccentricity ϵ) which are not measured directly, but which are only estimated for each centrality bin. Detailing the differences is instructive and points out systematic uncertainties that must be addressed before a fully quantitative estimate of K can be made.

One significant source of uncertainty in all such calculations is the lack of knowledge about the initial distribution of energy and matter that is relevant for the calculation of the initial eccentricity ϵ and the overlap area S_T . In Ref. [1], two initial conditions are presented representing different assumptions about the initial state, one

from a Monte Carlo Glauber (MCG) calculation and the other from a particular Color Glass Condensate (CGC) calculation [26]. For the MCG case the initial distribution of energy is defined by a combination of spatial coordinates of participating nucleons and binary collisions. The relative weights of the contributions follow the “two-component” model of Kharzeev and Nardi[27]:

$$\frac{dN_{ch}}{d\eta} = n_{pp} \left[(1-x) \frac{N_{part}}{2} + x N_{coll} \right] \quad (8)$$

with $x = 0.20$, the so-called “80:20” mixture. This nomenclature is potentially misleading: In central Au+Au collisions $N_{coll} \sim 6N_{part}$, which implies that the N_{part} term contributes only 40% of the matter while N_{coll} contributes 60%. It is also notable that the chosen value of $x = 0.20$ is not commonly used in the literature (e.g. Ref. [27]) and the experimental data at mid-rapidity at all beam energies is best described by $x = 0.13 \pm 0.01(stat) \pm 0.05(sys)$ [28].

Fig. 1 shows a new calculation of the eccentricity values using a modified version of the PHOBOS MC code [29] where we have incorporated the two-component model. Note that we use the standard nuclear parameters and no nucleon-nucleon hard core potential ($d = 0$). We calculate the eccentricity values from the Monte Carlo event-by-event by the following equation:

$$\epsilon_{part} = \frac{\sqrt{(\sigma_y^2 - \sigma_x^2)^2 + 4\sigma_{xy}^2}}{\sigma_y^2 + \sigma_x^2} \quad (9)$$

The notation ϵ_{part} will be used even for $x \neq 0$, i.e. when the weighting is not just for the participants. For comparisons with PHOBOS data, the second cumulant $\epsilon_{part}\{2\} = \sqrt{\langle \epsilon_{part}^2 \rangle}$ is used, since the event plane method is effectively a two particle correlation [25].

Fig. 1 shows the value of $\epsilon_{part}\{2\}$ for Au+Au collisions as a function of N_{part} for four values of $x = 0.0, 0.13, 0.20$, and 1.00 . The lower panel of Fig. 1 shows the ratio of each case relative to the $x = 0.00$ case. Results from Ref. [1] for $x = 0.20$ are also shown. We find that our results for $x = 0.20$ are systematically larger than their results. This discrepancy has been traced to the fact that the analysis in Ref. [1] uses a non-standard form for Eqn. 8, with a weight of one (as opposed to $1/2$) for the N_{part} term. This difference then gives a larger weighting for the spatial distribution of participants (i.e. lower x value), though there is no mapping onto a different exact x value given by Eqn. 8. We also show the eccentricity values for their Color Glass Condensate calculation for comparison, which interestingly track our $x = 1.00$ case, i.e. follow the density of the binary collisions, except in the most central collisions.

We have also checked the eccentricity fluctuations for the different x assumptions to see if this might offer an experimental method to discriminate between different x

FIG. 1: Glauber Monte Carlo eccentricities. Upper panel are the values for $\epsilon_{part}\{2\}$ as a function of the number of participants (calculated with different assumptions). Lower panel is the ratio of values relative to the Monte Carlo Glauber with $x=0.0$ case.

values. The results show that the event-to-event fluctuations in eccentricity are the same for all x cases within 3-6%. As one might expect, the fluctuations are somewhat smaller for the $x = 1.00$ case, since there are a larger number of binary collisions to smooth out the fluctuations compared with participants. However, this difference is affected by the spatial correlations between binary collisions and might even be further modified with inclusion of a nucleon-nucleon hard core potential (i.e. a non-zero value of d).

In addition to the differences in eccentricities even for the case of identical x values, there are a number of differences we have uncovered that we describe below.

- The average overlap area S_T is calculated using the

following equation:

$$S_T = 4\pi\sqrt{\sigma_x^2\sigma_y^2 - \sigma_{xy}^2} \quad (10)$$

corresponding to the area of the tilted ellipse. It should be noted that, in the literature, this equation appears in with various prefactors (e.g. π [25], 2π [18], and 4π [20]). The prefactor 4π gives a somewhat more intuitive result, as it yields the correct answer for the simple case of a disc with uniform density. This convention is utilized in the remainder of this paper. However, since the parton density is not uniform, it is possible that one should consider a smaller area (for example in a core/corona type picture).

In the extraction of the product (σc_s) from Eqn. 2, any multiplicative scaling of the vertical-axis quantity does not change the extracted results, but a multiplicative scaling of the horizontal-axis $\sim \frac{1}{S_T} \frac{dN}{dy}$ results in a linear change in (σc_s). However, we later note that simple multiplicative scaling of these quantities cancels in the determination η/s .

Finally, Ref. [1] does not calculate the overlap area S_T in the tilted (i.e. fluctuating event-by-event) frame. This turns out to be a minor (1-2%) difference, since the cross term σ_{xy} turns out to be relatively small compared to the other two moments.

- The experiments do not measure the parton density at early times, but instead measure $dN_{ch}/d\eta$ after freeze-out. The rapidity density dN_{ch}/dy is extracted from the measured $dN_{ch}/d\eta$ by multiplying by a simple estimate of the Jacobian factor of 1.15. However, this factor depends on the particle mix and momentum spectra, which are not measured by PHOBOS over their full acceptance. In the calculations of Drescher *et al.*, they have converted the $dN_{ch}/d\eta$ to dN_{ch}/dy with a factor 1.25; however, in our calculations we have used the factor utilized by PHOBOS of 1.15[25]. One can then convert from charged hadrons to all hadrons by assuming a multiplicative factor of 1.5. It should be noted that equating this hadron density to the *parton* density requires the additional assumption of local parton-hadron duality, with an exact factor of 1.0 scaling. Each of these factors enters as a linear scaling of the horizontal-axis quantity $\sim \frac{1}{S_T} \frac{dN}{dy}$.
- Ref. [1] calculates the average of the product (i.e. $\langle 1/S_T \times dN/dy \rangle$) in the Monte Carlo approach, for both CGC and Glauber. In contrast, since PHOBOS uses the measured $\langle dN/dy \rangle$ and calculate $\langle S_T \rangle$ for each centrality bin, they determine the product of averages (i.e. $\langle 1/S_T \rangle \langle dN/dy \rangle$). If one wants to use the average of the product, one cannot directly utilize the PHOBOS measured

$dN_{ch}/d\eta$ as a function of N_{part} , since one no longer has a model of the correlated fluctuations between the two quantities. Instead one must use a parametrization based on the MCG calculation event-by-event. Throughout this paper, we calculate the average of the product. We have also checked in the MCG calculation that taking the product of the averages and find differences in the extracted fit parameters of order 20%.

In our calculations, even though ϵ and S_T are calculated with different x values, $x = 0.13$ is always used to determine the charged particle multiplicity. This is because any case considered should have the correct particle multiplicity input (which is not described by significantly different x values within the two-component model). Thus, one should think of varying x as an arbitrary way of modifying the initial geometry while maintaining the correct multiplicity at a given centrality. If one were certain that the charged particle multiplicity constrains the geometry only around $x \approx 0.13$, then these other x scenarios might be ruled out. It is also notable that for the Cu+Cu data, there is a disagreement between this parametrization of the charged particle multiplicity at mid-rapidity by approximately 10% in the most central events.

One final comment about the experimental uncertainties, and how they enter the fits. The PHOBOS data are presented graphically with vertical lines for the quadrature sum of statistical and systematic uncertainties at the 90% Confidence Level. Thus, they are scaled down by 1.6 to convert them into one standard deviation uncertainties for input to a χ^2 fit. It is also not clear that the systematic uncertainties included here are uncorrelated point-to-point, which raises some issues about their inclusion in the standard χ^2 fit. Were the correlations known, the modified χ^2 fitting procedure developed in [30] could be used to properly account for the correlations when determining the errors on the fitted parameters. We make an estimate of this possible systematic uncertainty correlation in the next section.

EXTRACTING η/s

Fig. 2 shows the results from our calculations following the previously described prescription, using our MCG results with $x=0.00$, $x=0.13$, $x=1.00$. Given the experimental data for $v_2/\epsilon_{part}\{2\}$ as a function of transverse areal density, the fit procedure determines values and uncertainties for (σc_s) and $(\frac{v_2}{\epsilon})_{ih}$. Since only the product σc_s appears in the fit function, determination of the cross-section requires an explicit assumption for the sound speed. Taking $c_s = 1/\sqrt{3}$ for definiteness one obtains a cross-section value (in millibarns). The extracted

FIG. 2: Shown are the PHOBOS data for $v_2/\epsilon_{part}\{2\}$ versus $\langle \frac{1}{S_T} \frac{dN}{dy} \rangle \text{ fm}^{-2}$ where the $\epsilon_{part}\{2\}$ and S_T are calculated from a Monte Carlo Glauber. The figures are using $x=0.00$, $x=0.13$, $x=1.00$ (in the top, middle, and bottom panel respectively). Also shown are the best fit results in each case for the two fit parameters $(\sigma \times c_s)$ and $(v_2/\epsilon)_{ih}$. Additionally, following Eqn. 13, we calculate the $\eta/s \times 4\pi$ for each x assumed case. The quoted parameter uncertainties are one standard deviation fit uncertainties only, assuming the experimental systematic uncertainties are point-to-point uncorrelated.

values are shown in Fig. 2.

The extracted cross-section can be converted into a shear viscosity by using the results of a classical calculation [31] for massless particles at temperature T interacting with isotropic cross-section σ

$$\eta = 1.264 \frac{T}{\sigma} \quad (11)$$

giving

$$\frac{\eta}{s} = 1.264 \frac{T}{s\sigma} = 1.264 \frac{T}{4n\sigma} = 0.316 \frac{T}{\frac{(\sigma c_s)}{RS_T} \frac{dN}{dy}} \quad (12)$$

In the second step the entropy was assumed to be given by $s = 4n$, which follows from a definition of the number density using an ideal gas equation of state $n = P/T$ and the assumption of massless quanta with pressure $P = \frac{1}{3}\epsilon$ (here only ϵ is the energy density). We note that there is already a 10% ambiguity here since it is common practice in astrophysics to compute the number densities directly from the Bose distribution functions [32], leading to 3.6 units of entropy per photon.

Taking $T = 200$ MeV by assumption (another number with substantial uncertainty) and values for $\bar{R}$ from the Monte Carlo Glauber, one can calculate η/s for the most central Au+Au reactions at $\sqrt{s_{NN}} = 200$ GeV. The resulting values are shown in each panel of Fig. 2, and are summarized with later results in Fig. 6. It is notable that the initial conditions with larger eccentricity (e.g. $x = 1.00$) yield smaller values of η/s . This is counter-intuitive since a larger initial eccentricity should require a larger viscosity to reduce the v_2 down to the experimentally measured value. This result highlights that the extracted value of η/s comes from the curvature of the data points as a function of centrality and the $x = 1.00$ case indicates the largest degree of flattening (as seen in Fig. 2).

In principle each parameter has its own physics content, but it is interesting to check which parameters are necessary in order to extract η/s directly. Since $K = n\sigma\bar{R}$, one can directly write:

$$\frac{\eta}{s} = 0.32 \frac{T}{n\sigma} = 0.32 K_0 T \bar{R} \left[\frac{(v_2/\epsilon)_{ih}}{v_2/\epsilon} - 1 \right] \quad (13)$$

and quantities such as the speed of sound c_s and the transverse overlap area S_T do not explicitly appear. As a result, this form has the considerable advantage of explicitly demonstrating the parametric dependence of η/s on the input parameters. Conversely, this simple expression holds only for the 'minimalist' assumption for the K -dependence given by Eqn. 2, and therefore imposes the need to investigate alternative parametrizations of this dependence, as discussed in the following section.

It is interesting to compare our results with those from Ref. [1], who obtain $\eta/s \times 4\pi = 2.38$ using Monte Carlo

Glauber $x = 0.20$ (with the previously noted caveat regarding their non-standard x definition) and $\eta/s \times 4\pi = 1.38$ using Color Glass Condensate initial conditions. Before comparing these values to our results, we note that there is a mistake in their calculation of η/s in the CGC case. In the CGC case, in extracting the cross-section σ , they assume a speed of sound $c_s = 0.73 \times 1/\sqrt{3}$, but then use a density n calculated with the input $c_s = 1/\sqrt{3}$. As can be seen explicitly in our Eqn. 13, the speed of sound cancels out. Thus, the correct CGC value from their analysis is $\eta/s \times 4\pi = 1.89$. We also note that their quoted value of $n = 3.9 \text{ fm}^{-3}$ from reference [18] does not appear in that Letter, and must be converted for the difference in the S_T prefactor, the use of optical Glauber versus Monte Carlo differences, and a missing Jacobian factor.

Taking these observations into account, we note that the values from our calculation for $x = 0.13$ with $\eta/s \times 4\pi = 2.59 \pm 0.53$ for central Au+Au is similar to that from Ref. [1] for their $x = 0.20$ with $\eta/s \times 4\pi = 2.38$ (despite the mismatch in exact eccentricities and other differences outlined above). Similarly, our calculation with $x = 1.00$ gives $\eta/s \times 4\pi = 1.78 \pm 0.38$, similar to Ref. [1] for the CGC case with $\eta/s \times 4\pi = 1.89$ (with the correction described above).

Here we re-visit the issue of the handling of the PHOBOS experimental systematic uncertainties. In the above we have considered them to be point-to-point uncorrelated. Since we do not know the full correlation matrix, we consider two cases to estimate of the systematic uncertainty on the extracted η/s . If we allow the data points to move within the one standard deviation uncertainties in a correlated or anti-correlated manner (i.e. tilting the $v_2/\epsilon_{part}\{2\}$ values around the mid-central point), we find that for the $x = 0.13$ case, we obtain values of $\eta/s = 1.68$ (moving the central points down and the peripheral points up) and $\eta/s = 3.61$ (moving the central points up and the peripheral points down). We note that the χ^2 total is very large in all cases in part because the statistical uncertainties are quite small and some part of the systematic uncertainty is likely uncorrelated. Thus, as an approximate estimate, the true fit uncertainty from the experimental uncertainties alone is most likely twice as large as that shown in Fig. 2. For the $x = 0.13$ case, we then should state it as $\eta/s = 2.59 \pm 1.00$, instead of the previously quoted $\eta/s = 2.59 \pm 0.53$.

OTHER PARAMETRIZATIONS

It has already been noted that Eqn. 2 is not derived from any *a priori* theoretical expectation, but has been constructed to obey limiting functional forms at large and small K . Given this, it is of interest whether an alternative functional form might fit the available data equally well and still obey the same two limits. A sim-

FIG. 3: Shown are the PHOBOS data for $v_2/\epsilon_{part}\{2\}$ versus $\langle \frac{1}{S_T} \frac{dN}{dy} \rangle \text{ fm}^{-2}$ where the eccentricity and transverse overlap area are calculated from a Monte Carlo Glauber. The calculation uses $x=0.13$. Also shown are the best fit results (solid line) using the formulation with the Padé approximant motivated functional form, and then extracting the fit parameters $(\sigma \times c_s)$ and v_2/ϵ_{ih} . Additionally, following Eqn. 12, we calculate the $\eta/s \times 4\pi$. For comparison, we plot the curve for the same case with the standard fit (dashed line).

ple functional form (motivated by Padé approximants) is utilized here:

$$\frac{\frac{v_2}{\epsilon}}{(\frac{v_2}{\epsilon})_{ih}} = \frac{1 + A \frac{K}{K_0} + B \left(\frac{K}{K_0} \right)^2}{1 + C \frac{K}{K_0} + D \left(\frac{K}{K_0} \right)^2 + E \left(\frac{K}{K_0} \right)^3} \quad (14)$$

This equation obeys the large and small K limits as the previous parametrization, if $B = E$ and $C = A + 1$. Of course one can obtain an infinite set of such equations by expanding the number of terms in the numerator and denominator. For this case, we constrain ourselves to the case where $B = E = 1$ and $A = 1, C = 2$. Fig. 3 shows the best fit where the additional parameter D is allowed to vary (for the $x = 0.13$ case). There is an approximately 25% decrease in the ideal hydrodynamic value $(\frac{v_2}{\epsilon})_{ih}$, while the $\sigma = 4.97 \pm 2.38$ millibarns (assuming $c_s = 1/\sqrt{3}$) increases by about 25% relative to the previous value of 3.96 ± 0.55 , although with a larger uncertainty. This best fit corresponds to $D \approx 2$.

However, it turns out that the standard MINUIT χ^2 fit has returned an incorrect uncertainty range because of a non-parabolic shape of the χ^2 surface. The reason for this behavior is examined in Fig. 4, which shows all of the parameter fits with χ^2 values within one standard deviation of the minimum, the total χ^2 as a function of the extracted σc_s value, and the associated parameter values for D and $\frac{v_2}{\epsilon}_{ih}$.

FIG. 4: Upper panel shows the fit results with χ^2 values within 1σ of the minimum. Middle panel shows the total χ^2 as a function of the extracted σc_s value. Lower panel shows the associated parameter values for D (dashed) and $\frac{v_2}{\epsilon} \times 10$ for visibility (solid).

The presented χ^2 as a function of (σc_s) allows the determination of the uncertainty on σ at one-standard deviation to be $^{+25.0}_{-1.0}$ millibarns. Almost any arbitrarily large value for the cross-section σ gives an equally good description of the experimental data with an almost identical value for $\frac{v_2}{\epsilon}$ and an increasing value of D for larger σ values. Using Eqn. 12 to determine the corresponding values for η/s we find an allowed range of $\eta/s \times 4\pi$ from 2.55 all the way down 0.34 (well below the postulated bound).

These results indicate a certain fragility in the procedure outlined in Ref. [1] since a minimal modification of the parametrization amplifies the uncertainties in η/s by an order of magnitude. It is therefore important to investigate if there are *a priori* theoretical restrictions on the functional dependence of v_2/ϵ on the Knudsen number. For example, are there theoretical arguments that might constrain $D \sim 2$. In a simple transport scenario with centrality independent cross-section σ , temperature T , and speed of sound c_s , one might question why the underlying dynamics would change significantly with centrality (i.e. $D \gg 1$).

However, if obeying the two limits for K is insufficient

to determine the functional form, then one needs to make a proper theoretical argument about which types functional forms are truly relevant. There have been attempts to check the Knudsen number dependence with transport calculations and viscous hydrodynamic calculations [33], and these may lend support to the simple parametrization. However, if the parametrization is only tested in certain scenarios, then one has all the limitations of those particular scenarios and one cannot make more general conclusions.

QUANTUM LIMITS

One obvious feature of the above treatment is the lack of any explicit quantum bound on the value for η/s . Clearly if such a bound exists, then the experimental values for v_2/ϵ cannot approach the ideal hydrodynamic limit, and it is unlikely that a transport formalism that allows violations of the bound would be applicable to the determination of η/s in the vicinity of the bound. In this section we consider a modification of the formulation which explicitly incorporates the bound.

Following the original formulation of the bound [34], we assume that the mean free path λ cannot be smaller than the DeBroglie wavelength of the particle. A simple prescription incorporating this limit is to modify the mean free path accordingly:

$$\lambda = \frac{1}{n\sigma} \longrightarrow \frac{1}{n\sigma} \left[\frac{1}{1 - e^{-\langle p \rangle / n\sigma}} \right] \quad (15)$$

In the limit where $\langle p \rangle \ll n\sigma$, $\lambda = 1/\langle p \rangle$ (the DeBroglie wavelength), while the limit $\langle p \rangle \gg n\sigma$ gives the standard expression $\lambda = 1/(n\sigma)$. Note that we are using natural units throughout.

In relating these values to η/s we proceed as before

$$\frac{\eta}{s} = 0.316 \frac{T}{n\sigma} \longrightarrow 0.316 \frac{T}{n\sigma [1 - e^{-\langle p \rangle / n\sigma}]} \quad (16)$$

Taking $\langle p \rangle \approx 2.7T$ (relevant for massless, non-interacting particles) the high density limit gives $\eta/s \approx 0.316 T \times \lambda = 0.316T/(2.7T) = \frac{1.4}{4\pi}$. Thus, there is a modest inconsistency (at the 40% level) between this implementation and the exact bound value. Note that it is possible to enforce the precise value of the bound by requiring $\lambda \geq 0.7/\langle p \rangle$, but in the interest of a simpler heuristic treatment we do not consider this additional modification. We highlight that even in the presence of quantum effects the Knudsen number itself $K = \lambda/\bar{R}$ can come arbitrarily close to zero, for example in a neutron star where $\bar{R} \gg$ any other scale in the problem.

The expression for K as a function of $\frac{1}{S_T} \frac{dN}{dy}$ is:

$$K = \frac{\lambda}{\bar{R}} = \frac{1}{\bar{R}} \frac{1}{n\sigma} \left[\frac{1}{1 - e^{-2.7T/n\sigma}} \right] \quad (17)$$

FIG. 5: Shown are the PHOBOS data for $v_2/\epsilon_{part}\{2\}$ versus $\langle \frac{1}{S_T} \frac{dN}{dy} \rangle \text{ fm}^{-2}$ where the eccentricity and transverse overlap area are calculated from a Monte Carlo Glauber. The calculation uses $x=0.13$. Also shown are the best fit results using the formulation with the quantum bound correction limit (solid line), and then extracting the two fit parameters $(\sigma \times c_s)$ and $(v_2/\epsilon)_{ih}$. Additionally, following Eqn. 12, we calculate the $\eta/s \times 4\pi$. For comparison, we plot the curve for the same case without the quantum bound correction (dashed line).

$$K = \frac{1}{\sigma c_s \langle \frac{1}{S_T} \frac{dN}{dy} \rangle} \left[\frac{1}{1 - e^{-2.7T\bar{R}/(\sigma c_s \langle \frac{1}{S_T} \frac{dN}{dy} \rangle)}} \right] \quad (18)$$

However, when using this expression into Eqn. 2 one needs to know the dependence of $\bar{R}$ on $\langle \frac{1}{S_T} \frac{dN}{dy} \rangle$ before performing the fit. This dependence has been calculated with a Monte Carlo Glauber and then included in the fit to the experimental data.

The resulting value of the fit is shown in Fig. 5. It gives a slightly smaller value of $\sigma c_s = 3.45 \pm 0.43 (\times 1/\sqrt{3})$ millibarns. This modest change is not surprising since the starting value without the correction is already a factor of 2.5 away from the quantum bound. For systems even closer to the bound, the impact would be much more significant. Note however that the extracted value of η/s is almost $1/4\pi$ larger than that extracted without incorporating the bound. This is not at all unexpected since one has re-interpreted the associated η/s value with the asymptotic limit of the fit function.

DISCUSSION

In this paper, we are not advocating the Knudsen number formalism as a rigorous method of extracting η/s . Rather we are highlighting various issues with this methodology and note areas where systematic uncertainties are common to various methods that have been pro-

FIG. 6: The solid points are the extracted values of η/s as a function of Monte Carlo Glauber parameter x and for the quantum limit and modified Knudsen number parametrization cases. The vertical uncertainty lines are the one standard deviation uncertainties from the fits to the experimental data assuming the PHOBOS systematic uncertainties are point-to-point uncorrelated. An estimate of the systematic uncertainty on η/s , if the experimental systematic uncertainties are correlated (as discussed in the text), is shown as a box for the $x = 0.13$ case. Also shown as open symbols are the values extracted by Drescher *et al.* for Glauber and CGC initial conditions.

posed for extracting η/s . There are three main conclusions.

1. As has been previously observed, any method for extracting η/s will be sensitive to the details of the initial conditions, and in particular the spatial distribution (and fluctuations) of the deposited energy density. This induces a strong sensitivity to the assumed ratio x of binary collisions to participants in the Monte Carlo Glauber formalism since a modest centrality dependent change in the spatial distribution substantially changes the asymptotic behavior implied by the fit. This is particularly true because the experimental data does not have small enough uncertainties for central Au+Au events to determine whether an asymptotic limit has been reached. This is the main reason why choosing a different functional form for the Knudsen number parametrization allows almost any value for η/s to be extracted, as demonstrated above.

In this paper we do not consider the Color Glass Condensate initial conditions in detail. However we note that there are at least two formulations that give significantly different results. These include calculations such as Ref. [35] which do not include fluctuations, and Ref.

[26] which includes fluctuations and is the basis of the calculations by Drescher *et al.* shown in Fig. 1. The differences in CGC initial condition eccentricities are as large as the differences between Monte Carlo Glauber x values, and thus this also needs to be addressed and reconciled.

These initial geometry uncertainties generally have a larger influence on this extraction method since a subtle difference in centrality dependence (i.e. curvature) can dramatically change the fit. Note that while Ref. [25] finds the change in eccentricity from $x = 0.0$ to $x = 0.13$ for central Au+Au events to be 15% and thus considered small, we find that the change in the centrality dependence modifies the extracted value of η/s by more than 50%.

These uncertainties certainly also influence other methods of extracting η/s . We note that in the viscous hydrodynamic calculations in Ref. [12], they consider two sets of initial conditions. In the Glauber case they utilize an optical model without fluctuations, and utilize the $x = 1.00$ case. In contrast, Ref. [10] utilizes participants for initial conditions (i.e. $x = 0.00$). In the case of constraints on η/s from charm and bottom elliptic flow v_2 [9] the extractions of η/s will also depend on the initial conditions and the same scrutiny and propagation of uncertainties is needed. In Ref. [36] they utilize an optical Glauber model without fluctuations and wounded nucleons (i.e. $x = 0.00$), while in Ref. [37] they state that for impact parameter $b = 7$ fm the eccentricity is $\epsilon = 0.6$.

These observations highlight the critical importance of a reproducible set of publicly available code for generating what are often simply referred to as “Glauber” initial conditions. All publications need a detailed specification of all relevant features of the Glauber calculation, including 1) the x value, 2) Glauber parameters for the Woods-Saxon distribution, 3) any d exclusion radius and re-weighting of the radius value, 4) any outer radius cut-off, 5) whether fluctuations in the reaction plane direction are included (as seen in Eqn. 9) 6) whether the result is not a Monte Carlo but instead an optical Glauber extraction. Many of the individual uncertainties related to these parameters have previously been considered minor (i.e. 20% or less).

2. Even if one accepts the assumptions of the formalism from Ref. [1], there are significant uncertainties in the parameters characterizing the medium on time scales corresponding to the largest gradients, i.e. T , c_s and $\bar{R}$. Since these values vary as a function of both the space and time coordinates, one needs to specify the precise time and space interval over which the averaging is performed. It is also necessary to demonstrate that such averaging of intermediate quantities is handled in a self-consistent fashion when deriving other averaged quantities (such as η/s). For example, the speed of sound c_s is introduced into Eqn. 5 when estimating the characteristic time over which gradients develop. Absent a detailed

simulation, the speed of sound in such an expression is an ill-determined average over times prior to the desired characteristic time. Nor is it obvious that this is same time-average assumed for other quantities such as T , $\bar{R}$, λ , etc.

Moreover, there is also a potential inconsistency with the parameters used in studies up to this point. The temperature, parton density, speed of sound, and interaction cross-sections are not independent parameters. In fact at zero baryon density, the temperature determines all of the others. As an explicit example, a temperature of $T = 200$ MeV is inconsistent with the speed of sound of $1/\sqrt{3}$ when comparing with lattice QCD results at zero baryon chemical potential [38]. Also, temperature and parton density can be translated into T and ϵ (energy density) via the QCD equation of state. While it seems reasonable that the temperature, density and speed of sound are approximately constant over the range of densities for Cu+Cu and Au+Au collisions at a single colliding energy (e.g. $\sqrt{s_{NN}} = 200$ GeV) considered here, this is not expected to be true at asymptotically high densities. Even though there are no experimental data points at such densities, and one extracts $\sigma \times c_s$ and η/s at the density corresponding to Au+Au central collisions, even small changes can systematically alter the centrality dependence, modifying the extracted value of K , and thus η/s . One must also consider the possibility of temperature dependent cross-sections in medium, something not addressed so far. Again, what are often dismissed as small centrality dependencies can modify the curvature of the data and have an unexpectedly large impact on η/s .

We note that there has been a recent attempt to calibrate the simple analytic approach discussed here, utilizing viscous hydrodynamics calculations [33]. These studies have already revealed an ambiguity in the value of η/s and the equation of state. Additionally, any such calibration will have the same caveats and limitations of the existing viscous hydrodynamic calculations (with one such example being the absence of a hadronic phase after freeze-out).

3. In the formulation discussed in this paper, the extracted value of η/s depends on whether or not a lower bound is explicitly introduced. Thus, if a lower bound on the viscosity does in fact exist, then η/s extractions which do not incorporate it in their formalism will ultimately be unreliable. Conversely, approaches which enforce such a quantum bound on η/s obviously cannot extract values below the bound. Thus one could never falsify the existence of such a bound. This is in contrast to full viscous hydrodynamic calculations and comparisons which do not rely on microscopic modeling of transport phenomena.

This raises the question as to whether the calculational framework discussed in Drescher *et al.*, and this work, is valid in the strong-coupling limit, i.e. at $\eta/s = 1/4\pi$. A

standard Boltzmann transport calculation is the opposite limit from hydrodynamic calculation, which assume a continuum hypothesis. The theory community has explored both approaches with great benefit, and in both cases one can attempt to push the models past their nominal domains of applicability. If the viscous corrections to the ideal hydrodynamics are too large, then they violate the gradient expansion made in the small η/s limit. In the Boltzmann transport approach (e.g. a parton cascade), the quasi-particle widths become of same order as the masses when the mean free paths are comparable to the DeBroglie wavelengths (i.e. $\Gamma/m \approx 1$) [39]. As an example, if one ignored multi-particle quantum effects in a gas of cold atoms near the BEC transition that would have a dramatic impact on the physics picture. Thus, in this case, it is not clear how to determine the systematic uncertainties and overall physical picture.

SUMMARY

The formalism for relating η/s to the Knudsen number has attracted much recent attention since it offers a tantalizing possibility of extracting transport properties almost directly from experimental data. However, several important issues need to be addressed consistently before one can consider this approach to produce anything more than order-of-magnitude estimates. The linearity of η/s with T , c_s , and even $\bar{R}$ makes a serious evaluation of their uncertainties of utmost important. One must also consider the fact that c_s is a function of temperature due to the QCD equation of state itself. The final result for η/s is quite sensitive to Monte Carlo Glauber parameters, and particularly the parameter x which controls the balance between N_{part} and N_{coll} . Finally, implementing a lower bound to η/s , for instance as we have presented in this work, has a substantial effect on the extracted value, particularly since previous calculations find values so close to the bound already.
